ABSTRACT

In April 2012, a specimen of giant tiger prawn, Penaeus monodon, was captured by an artisanal bottom trawlboat on the northern continental shelf of Rio Grande do Norte State, northeastern Brazil. This specimen, a female, was collected from a 4-meter depth, had a partial total length of 249.6 mm and weighted 173 g. This is the second report of P. monodon off the coast of Rio Grande do Norte, 11 years after the first record, which suggests an ongoing southward expansion of this species in northeastern Brazil.

Keywords: Penaeidae, Penaeus monodon, occurrence report, non-indigenous species, shrimp farming.

RESUMO

Em abril de 2012, um exemplar do camarão tigre gigante, Penaeus monodon, foi capturado por uma embarcação artesanal, utilizando rede de arrasto de fundo na região costeira da plataforma continental setentrional do Estado do Rio Grande do Norte, Nordeste do Brasil. O espécime, do sexo feminino, foi coletado a 4 metros de profundidade e possuía um comprimento total parcial de 249.6 mm e 173 g de peso total. Este é o segundo registro de P. monodon para o litoral do Rio Grande do Norte, 11 anos após o primeiro registro, o que sugere a expansão para o sul desta espécie no Nordeste do Brasil.

Palavras-chaves: Penaeidae, Penaeus monodon, registro de ocorrência, espécie exótica, carcinicultura.

INTRODUCTION

Penaeus monodon Fabricius, 1798, is a prawn species belonging to the Penaeidae family. It is native from the western Indian Ocean and southeastern Pacific Ocean, and has been recorded in southern Japan, Korea, China, Taiwan, Philippines, Vietnam, Cambodia, Malaysia, Singapore, Indonesia, Papua New Guinea, Australia, Thailand, Myanmar, Bangladesh, Sri Lanka, India, Pakistan, Tanzania, Madagascar, South Africa and the Red Sea (Motoh, 1981; FAO, 2012; Fuller et al., 2014). It is also known as giant tiger prawn, because of its great size and the presence of brown and yellow-colored stripes along its abdomen, carapace, flippers and appendices. According to Holthuis (1980), this species inhabits the continental shelf, up to 100 meters deep, in predominately sandy or muddy bottoms. It also shows outstanding ontogenetic distribution, with juveniles inhabiting the estuary and adults migrating to the sea. When adults, the individuals may reach a total length of 330 mm, with the females being larger than males (FAO, 2012).

Giant tiger prawn has been widely cultivated out of its natural distribution area, for instance, in both sides of Atlantic, so that populations have already settled in many locations as made up of individuals having escaped from shrimp farming ponds, namely southeastern Atlantic (Sahel & West Africa Club, 2006; Global Biodiversity Information Facility, 2013), northwestern Atlantic and Gulf of Mexico (Fuller et al., 2014), Caribbean (Gómez-Lemos & Campos 2008), and the southwestern Atlantic, from Colombia to Brazil (Coelho et al., 2001; Silva et al., 2002; Aguado & Sayegh, 2007; Cintra et al., 2011; Aguirre-Pabón et al., 2015).

According to Wakida-Kusunoki et al. (2013), ecological impacts by the giant tiger prawn in non-indigenous environments are poorly known. However, considering that the species is a predator of limp-bodied invertebrates, and behaves more aggressively than native prawns, it may produce negative ecological effects, including higher consumption of small crab species, bivalves and gastropods; transmission of pathogens; interspecific competition for space and food, interference with the behavior and/or reproductive success, and direct predation of native prawns (e.g., Marte, 1980; De La Vega et al., 2004; Molnar et al., 2008; Knott et al., 2012; Wakida-Kusunoki et al., 2013).

In the early 1980s, P. monodon was introduced into Brazilian shrimp farms through the pioneer “Prawn Project”, developed by the government of Rio Grande do Norte State, which was considered particularly relevant for the development of shrimp farming in the country (Lopes et al., 2009). Extensive cultivations of P. monodon had a promising start but soon several harvest failures occurred due to high cost of feeds so that its rearing was definitely dismissed as economically unfeasible. Later on, this species was replaced by Litopenaeus vannamei (Leão et al., 2011), which presented more satisfactory qualities and productive results (Barbieri Júnior & Ostensk Neto, 2001).

Several authors relate the pervasive presence of P. monodon off the Brazilian coast, from the states of Amapá to São Paulo (e.g., Fausto-Filho, 1987; Rodrigues et al., 2000; Coelho et al., 2001; Santos & Coelho, 2002; Silva et al., 2002; Migotto & Marques, 2003; Tavares & Mendonça, 2004; Santos & Coelho, 2007; Instituto Hórus, 2009; Cintra et al., 2011; Silva & Barros, 2011; Leão et al., 2011). In addition, there are three anecdotal records of P. monodon off the coast of Ceará State, in a westward position in relation to the one herein reported.

A project dealing with the occurrence of non-indigenous species on the continental shelf of Northeast Brazil reported the first specimen of P. monodon off Rio Grande do Norte State, caught by shrimp trawler at 10 – 20 meters depth in the period from April to July, 2001, but with no specific location given (Santos & Coelho, 2007).

Thus, the aim of this study was report the second time, after about 11 years of their first record, the confirmation of giant tiger prawns, P. monodon, invading the coast of Rio Grande do Norte, northeastern Brazil.

MATERIAL AND METHODS

In April 2012, a specimen of the giant tiger prawn, P. monodon, was captured by an artisanal craft, by using a bottom trawl at the coastal region of northern shelf of Rio Grande do Norte, Galinhos county, northeastern Brazil (Figure 1). At the time of capture, trawling was being made at 05°05’17.4”S - 36°15’17.4”W longitude, about 700 meters far from the Galinhos beach coastline, at 4-meters deep. The sex of the animal was identified by the presence of the thelycum, and the partial measurements of total length (PTL), carapace length (PCL), carapace width (CW) and carapace depth (CD) were performed with the aid of a digital caliper ruler; total weight (TW) was obtained by using a digital precision scale. The specimen was deposited in the scientific collection of the Grupo de Estudos em Ecologia e Fisiologia de Animais Aquáticos at Rio Grande do Norte Federal University, voucher number GEEFAA/UFRN-194.
RESULTS AND DISCUSSION

The female specimen of *P. monodon* was captured in April, 2012, and measured 249.59 mm PTL, 75.43 mm PCL and 173 g TW (Table I; Figure 2). The morphometric values obtained were close to average ones found in the literature (e.g., Santos & Coelho, 2002 e 2007; Cintra et al., 2011; Natarajan et al., 2011; Wakida-Kusunoki et al., 2013; Fuller et al., 2014). According to Motoh (1981), females of *P. monodon* with carapace length greater than 47 mm and a structurally complete thelycum are sexually mature and since the identified individual possessed these traits, it is possible that at least one spawning had already occurred.

This is the second confirmed report of *P. monodon* occurrence in the shore of Rio Grande do Norte, subsequent to its first occurrence, 11 years ago. Because both adult and juvenile individuals have been found on the coast of northeastern Brazil (Coelho et al., 2001; Santos & Coelho, 2002) it is certain that this animal is reproducing and completing its entire life cycle in Brazilian waters.

Considering the records gathered here, it might be inferred that the distribution of *P. monodon* in the southwestern Atlantic goes from Colombia to São
Paulo (Brazil), a coastline of approximately 10,000 km. This collection likely represents a southward expansion of the known Atlantic population, a fact which is not unexpected as larvae would be transported southward by the Brazil Current.

As of yet, there is no evidence of changing species composition in the biocensis caught by artisanal fisheries. There has been no effort to sample or gather occurrence records in Brazil that could be used to determine the population structure of the species on the Brazilian coast. A more effective sampling effort might reduce the current geographic gaps in existing records. Studies from the region to the south of São Paulo could reveal the southern limit of the species and track its expansion. Finally, more studies are needed in order to investigate the dynamic establishment of the Brazilian coast.
